ABSTRACT

We investigate the effects of $\alpha$-element enhancement and the thermally pulsing-asymptotic giant branch (TP-AGB) stars on the surface brightness fluctuation (SBF) magnitudes and broadband colors of simple stellar populations and compare to the empirical calibrations. We consider a wide range of ages and metallicities using the recently updated Teramo BaSTI isochrones. We find that the $\alpha$-element-enhanced $I$-band SBF magnitudes are about 0.35 mag brighter and their integrated $V-I$ colors are about 0.02 mag redder, mostly because of oxygen-enhancement effects on the upper red giant branch and AGB. We also demonstrate, using both the Teramo BaSTI and Padova isochrones, the acute sensitivity of SBF magnitudes to the presence of TP-AGB stars, particularly in the near-IR, but in the $I$ band as well. Empirical SBF trends therefore hold great promise for constraining this important but still highly uncertain stage of stellar evolution. In a similar vein, non-negligible disparities are found among several different models available in the literature due to intrinsic model uncertainties.

Key words: galaxies: stellar content – stars: abundances – stars: evolution

Online-only material: color figures

1. INTRODUCTION

The surface brightness fluctuation (SBF) method, which measures the intrinsic pixel-to-pixel intensity variance in a galaxy image, is widely used as one of the most powerful distance indicators as well as a useful tool for probing stellar populations in the integrated light of early-type galaxies and spiral bulges. It is now a well-known fact that SBF magnitudes vary as a function of galaxy colors (e.g., Tonry et al. 2001; Jensen et al. 2003). For instance, empirical relations show that galaxies with redder $V-I$ colors have fainter $I$-band SBF magnitudes (e.g., Tonry 1991; Tonry et al. 1997, 2001). Moreover, there have been some suggestions that bluer dwarf elliptical galaxies have a shallower slope in the $V-I$ versus $I$-band SBF magnitude diagram compared to the redder, massive galaxies (e.g., Blakeslee et al. 2001; Mei et al. 2005; Mieske et al. 2006).

From the observational side, it is relatively well established that the red massive early-type galaxies have at least some lighter elements enhanced relative to Fe-peak elements by about $0.3-0.4$ dex (e.g., Worthey et al. 1992; Lee & Worthey 2005). This abundance pattern may resemble that of halo $\alpha$-element enhancement, although this has not been thoroughly proven (Worthey 1998). There are several theoretical spectrophotometric studies that consider $\alpha$-enhancement in order to address those observations (e.g., Thomas et al. 2003; Lee & Worthey 2005; Coelho et al. 2007; Schiavon 2007; Lee et al. 2009). However, only solar-scaled SBF model’s predictions have been calculated in the past (Worthey 1993, 1994; Liu et al. 2000; Blakeslee et al. 2001; Lee 2001; Mei et al. 2001; Cantiello et al. 2003; Mouhcine et al. 2005; Raimondo et al. 2005; Marín-Franch & Aparicio 2006).

Moreover, because of the nature of the SBF method, which is far more sensitive to the brighter stars compared to the integrated photometry, thermally pulsing-asymptotic giant branch (TP-AGB) phase is predominately important (e.g., Liu et al. 2000; Mouhcine et al. 2005; Raimondo et al. 2005). The TP-AGB phase is the last stage of AGB evolution. After the high-mass main-sequence (MS) stars and supergiants fade away, it is AGB stars that dominate the integrated bolometric light until full-fledged red giant branch (RGB) stars are looming. After $t > 2$ Gyr, the RGB tip becomes nearly as bright as the AGB tip but is much more numerous populated, by nearly a factor of 10 (e.g., Ferraro et al. 2004; Mucciarelli et al. 2009). The recent development of detailed studies of TP-AGBs (e.g., Maraston 2005; Maraston et al. 2006; Lee et al. 2007b; Marigo et al. 2008) can be thoroughly inspected with observations by the SBF method. In this study, we explore the question of how the $\alpha$-elements (e.g., O, Mg, Si, S, Ca, Ti) and TP-AGBs affect the galaxy colors and SBF magnitudes.

2. MODELS

The present stellar population synthesis models are based upon the Teramo BaSTI isochrones$^4$ (Pietrinferni et al. 2004, 2006; Cordier et al. 2007). The models we compute are all single starbursts, characterized by a single age and metallicity. In reality, galaxies are generally composed of mixtures of stellar populations with a range of ages and metallicities.

We have, however, deliberately employed a simplified (i.e., single burst) star formation prescription in this study so that we can explore the importance of varying one parameter, namely the $\alpha$-element enhancement. In this regard, our single-burst models approximately represent the luminosity weighted mean age and metallicity for the stellar systems in question. Following our previous models (Lee et al. 2007b, 2009), we employ the standard Salpeter (1955) initial mass function (IMF). The low-mass cutoff is $0.5 M_\odot$ as given in the Teramo BaSTI isochrones. We do not consider the stochastic nature of the TP-AGB in this study. We merely calculate the SBF magnitudes and the broadband colors using the isochrones as they are available.

$^4$ http://193.204.1.62/index.html
from stellar modelers’ Web sites. It is our intention though for future study to investigate those stochastic variations.

In Section 2.2, we elaborate the nature of the $\alpha$-enhancement in stellar models, particularly the different definitions and degrees of $\alpha$-element mixture by different groups and their implications.

### 2.1. HRDs and CMDs

Here we present, for the first time, $\alpha$-element-enhanced SBF models and compare them with observations. Before we fully examine the model outputs and the comparisons with observations, however, we first look into the $\alpha$-element effects at the H−R diagrams (HRDs) and the color−magnitude diagrams (CMDs) as well as at the emergent fluxes. The reason that we primarily employ the Teramo BaSTI Isochrones in this study is because the Teramo BaSTI stellar models provide both solar-scaled and $\alpha$-enhanced isochrones with correct matching of stellar model atmospheres (Cassisi et al. 2004) all the way to the full TP-AGB stages that are crucial for the SBF calculations.

Figure 1 contrasts the solar-scaled standard (sss; by “standard,” we indicate that they adopt no convective-core overshooting) Teramo BaSTI isochrones with $\sim$0.4 dex $\alpha$-element-enhanced ones (aes) in the log $L$$_{eff}$ versus log $L$/$L$$_{\odot}$ plane. At solar metallicity ($Z = 0.02$), the Teramo BaSTI sss and aes isochrones with (right panels) and without (left panels) TP-AGBs are compared at three given ages (1, 5, 13 Gyr). The sss isochrones are solid lines, while the aes ones are depicted with dashed lines. To guide the eye, RGB tips are denoted with squares for the sss and triangles for the aes, respectively. Bottom panels show the details in the giant branch. The RGB temperatures are generally slightly warmer ($\sim$45 K) with $\alpha$-enhancement at fixed total metallicity, partly reflecting the depression of iron abundance. Note also from the right panels that at younger ages ($t < 5$ Gyr), the TP-AGBs go far cooler and brighter compared to their RGB tips.

Figure 2. Similar to Figure 1, but here we display the comparison of the sss and the aes Teramo BaSTI isochrones in the $V - I$ vs. $I$ CMDs. Symbols for the RGB tips and the TP-AGBs are same as in Figure 1. Note from the left panels that the $\alpha$-enhanced RGBs, especially at the upper part ($I < -2$), are relatively brighter and redder in this $V - I$ vs. $I$ CMDs compared to that of the solar-scaled. Similarly, it is noted from the right panels that the $\alpha$-enhanced TP-AGBs are also comparatively brighter and redder than the solar-scaled models. Moreover, it is seen from the right panels that at younger ages ($t < 5$ Gyr), the TP-AGBs go far redder compared to their RGB tips.

(A color version of this figure is available in the online journal.)
Figure 3. At 4000 K, log g = 0.5, and [Fe/H] = 0, the solar-scaled spectrum is divided by the 0.15 dex carbon-enhanced spectrum (upper left), the 0.3 dex nitrogen-enhanced spectrum (upper right), the 0.3 dex oxygen-enhanced spectrum (lower left), and the 0.3 dex iron-enhanced spectrum (lower right), respectively. UBVI-band filter locations are indicated. It is seen from the lower left panel that the oxygen enhancement makes the higher V band. From the upper panels it is noted that carbon and nitrogen-enhancements make the bluer V−I color at this temperature and surface gravity of the typical upper RGB and AGB. From the comparison of C-, N-, and O-enhanced cases, it is identified that many features around the I-band are CN bands and that they are more sensitive to the carbon abundance than to the nitrogen. Furthermore, it is seen from the lower right panel that many strong metal absorption line features are mostly located within the UBV bandpass. Note also that the I-band luminosity is relatively insensitive to the iron abundance.

(A color version of this figure is available in the online journal.)

2002; Vandenberg et al. 2006; Dotter et al. 2007a, 2007b, 2008) besides the Teramo BaSTI ones of Pietrinferni et al. (2006) that we employ in this study. One should, however, carefully examine (1) whether their α-element enhancement is defined at fixed total metallicity, Z or at fixed [Fe/H] and (2) how their α-element mixture is defined for their α-element-enhanced stellar models. In this study, we are contrasting the Teramo BaSTI stellar models with the Dartmouth ones (Dotter et al. 2008) and only note that different α-element mixtures by different groups have significant differences even though they are all commonly referred to as “α-element-enhanced stellar models.”

We have scrutinized, for example, the differences between Figure 1 of this paper and the results shown by Dotter et al. (2007a). Compared to our Figure 1, Figure 11 of Dotter et al. (2007a) shows almost no temperature changes, although they are similarly α-element-enhanced isochrones at fixed Z. The culprit is the α-element mixture. Although the Teramo BaSTI α-enhanced stellar models are of [α/Fe] ~0.4 dex, this is an average only. The Dartmouth models’ α-enhanced mix, in contrast, is a constant enhancement of all α-elements with respect to solar ratios. From inspection of Table 1 of Pietrinferni et al. (2006), their oxygen abundance is very high, close to the Dartmouth models’ [α/Fe] = +0.8 dex value. With this information in mind, the behavior in the HRD of Teramo BaSTI’s α-enhanced isochrones makes sense if they are compared with Figure 7 (oxygen-enhanced) in Dotter et al. (2007a). It is, in fact, the main reason why the New Standard Stellar Population Models (NSSPM) project has opened up new windows on element-by-element variations in order to decipher the rather cryptic collection of α-element mixtures (Dotter et al. 2007a; Lee et al. 2009).

It would be useful to compare different sets of α-enhanced stellar population models to see if they predict the same effects of α-enhancement on SBF. Unfortunately, we do not have the luxury of investigating several different versions of α-enhanced SBF models at the moment. Padova isochrones and stellar evolutionary tracks are perhaps more sophisticated at the TP-AGB stages compared to the Teramo BaSTI ones (e.g., Marigo et al. 20085), but the Padova ones do not yet provide the matching α-enhanced stellar evolutionary tracks and isochrones. Dotter et al. (2008; Dartmouth stellar evolutionary models), Kim et al. (2002; Yonsei-Yale models), and Vandenberg et al. (2006; Victoria-Regina models) all do provide the α-enhanced stellar models as well as the solar-scaled ones, but they do not provide the matching TP-AGB stages that are crucial for the SBF models. These three sets are of keen interest because they present the α-enhanced stellar models at fixed [Fe/H] instead of at fixed Z as the Teramo BaSTI stellar models do. Regarding the α-enhancement at fixed Z, a depressed Fe abundance preserves the total metallicity. For instance, in the Teramo BaSTI stellar models, there is about 0.35 dex [Fe/H] shift at fixed total metallicity, Z, between the solar-scaled (sss; solid lines) and the α-enhanced (aes; dashed lines) models. The case of fixed [Fe/H] is, alas, also less than perfectly straightforward. In that case, the enhancement of the α-elements increases the overall metallicity, and therefore either the abundance of hydrogen or helium (or both) must be modified in order to compensate for the increased Z.

Moreover, there is the stellar atmosphere (emergent flux) issue. The Teramo BaSTI α-enhanced stellar models incorporate the matching α-enhanced stellar model atmospheres self-consistently in order to generate the observables (magnitudes and colors) as described in Cassisi et al. (2004). All the other α-enhanced stellar models, however, employ the solar-scaled stellar atmosphere for their calculations of α-enhanced model observables. It would be useful to have α-enhanced models at fixed [Fe/H] from the Teramo BaSTI group, as well as at fixed Z, so that the effects of the α-element variation could be seen more directly, instead of mixing in the effects of Fe depression for the α-enhanced models at fixed Z (Salaris et al. 1993). In the same context, we are also looking forward to implementing the Padova α-enhanced stellar models with matching α-enhanced stellar model atmospheres as they become available.

Figure 3 demonstrates how the enhancement of each element (carbon, nitrogen, oxygen, and iron) modifies the emergent fluxes at 4000 K and log g = 0.5, which is the typical temperature and surface gravity of the upper RGBs and AGBs. The lower left panel of Figure 3 illuminates that the oxygen enhancement generates a brighter I-band luminosity and a redder V−I color. From Table 1, it is noted that the V−I color becomes 0.031 mag redder because of the 0.3 dex oxygen enhancement. Being a dominant α-element (e.g., O, Mg, Si, S, Ca, Ti), this behavior from the oxygen-enhanced spectrum is very useful in order to understand the V−I colors and I-band magnitudes seen in Figure 2 as well as the model results in Figure 4 that

5 Table 1 of Marigo et al. (2008) lists the available stellar isochrones including the TP-AGB phase. Marigo et al. (2008) note that the TP-AGB of the Teramo BaSTI isochrones by Cordier et al. (2007) was computed in a rather crude way, i.e., without considering the third dredge-up events (carbon star formation) and hot bottom burning nucleosynthesis.
we discuss in the following section. The upper panels illustrate the carbon- and nitrogen-enhanced spectra again at 4000 K and log $g = 0.5$. They are, in general, displaying the opposite from what we see in the lower left panel of Figure 3. By comparing the C-, N-, and O-enhanced spectra, it is interesting to find that many features around the $I$ band are CN bands, and they are more sensitive to carbon abundance than to nitrogen. The oxygen-enhanced spectrum in the lower left panel of Figure 3 illustrates that increasing oxygen abundance soaks up more C into the CO molecule, decreasing C$_2$, CH, and CN feature strengths.

The lower right panel of Figure 3 shows the iron-enhanced spectrum at 4000 K and log $g = 0.5$. It is evident that many strong iron absorption line features occur around the $UBV$ bandpasses. From Table 1, it is noted that the $U - B$ color becomes 0.084 mag redder because of the 0.3 dex iron enhancement. Moreover, it is worth emphasizing that $I$-band luminosity is relatively insensitive to the iron abundance. The lower right panel of Figure 3 is quite helpful in understanding the observed color-magnitude effects because the $\alpha$-enhanced Teramo BaSTI stellar models are essentially equivalent to Fe-depressed ones.

Figure 4 shows our new $I$-band SBF model calculations (aes: $\alpha$-enhanced standard, sss: solar-scaled standard, where “standard” again means no convective core overshooting) as a function of integrated $V - I$ colors based upon the recently updated (after 2008 May) Teramo BaSTI isochrones. Two observational fiducial lines (thick bent straight lines) are overlaid with our theoretical models. The line on the blue side is $I$-band SBF Mag = $-2.25 + 2.44 \times [(V - I) - 1.00]$ from Mieske et al. (2006) for dwarf blue galaxies, while the line on the red side is $I$-band SBF Mag = $-1.68 + 4.5 \times [(V - I) - 1.15]$ from Tonry et al. (2000) for massive red galaxies. It is worth mentioning here that we use the observational fiducial lines merely as a “sanity check.” As we mentioned in Section 2, we do not consider the stochastic nature of the TP-AGB in this study. Therefore, we want to make it clear that our aim in this study is the blunt investigation of the effects of $\alpha$-element enhancement and the TP-AGB stars on the SBF magnitudes and broadband colors of simple stellar populations.

Compared to our earlier results (Lee et al. 2007a), the differences between the solar-scaled and the $\alpha$-enhanced models are smaller mainly because of the Teramo BaSTI isochrones updates (due to the low temperature opacities by Ferguson et al. 2005 for the $\alpha$-enhanced stellar models). At solar metallicity ($Z = 0.02$, filled squares), it is found from Figure 4 (also from Table 3) that the $\alpha$-enhanced models become about 0.02 mag redder and 0.35 mag brighter in this integrated $V - I$ versus $I$-band SBF magnitude plane compared to the solar-scaled ones mostly because of the oxygen enhancement as we noted in Figures 2 and 3. The right panel of Figure 4 displays the integrated $V - I$ colors versus $I$-band SBF magnitudes when the TP-AGBs are not included in the calculations. The general trend of the $\alpha$-enhanced models at solar metallicity ($Z = 0.02$, filled squares) becoming redder and brighter compared to the solar-scaled ones for $t \geq 1$ Gyr is mostly intact. It is seen, however, that the $I$-band SBF magnitudes are much too faint without the TP-AGBs to match the observations, especially at the metal-poor end.

Figure 5 is similar to Figure 2, but here displays the comparison of the sss and the aes Teramo BaSTI isochrones in $V - I$ versus $I$ CMDs at $Z = 0.0003$. It is important to note here that compared to Figure 2, the $V - I$ colors and the $I$-band magnitudes are hardly changed with the $\alpha$-enhancement on this very metal-poor side even at the upper RGB. It explains the comparatively smaller effects of $\alpha$-enhancement on SBF models and broadband colors.

3. RESULTS

Having discussed the nature of the $\alpha$-element enhancement in terms of the isochrones and the emergent fluxes, we now present the integrated $\alpha$-enhanced SBF models and broadband colors. Following our initial results on this topic (Lee et al. 2007a), there have been critical updates from the Teramo BaSTI stellar models lately. The $\alpha$-enhanced isochrones and stellar evolutionary tracks have been recomputed for $Z > 0.001$ after employing the low-temperature opacities by Ferguson et al. (2005). $^6$

Figure 4 shows our new $I$-band SBF model calculations (aes: $\alpha$-enhanced standard, sss: solar-scaled standard, where “standard” again means no convective core overshooting) as a function of integrated $V - I$ colors based upon the recently updated (after 2008 May) Teramo BaSTI isochrones. Two observational fiducial lines (thick bent straight lines) are overlaid with our theoretical models. The line on the blue side is $I$-band SBF Mag = $-2.25 + 2.44 \times [(V - I) - 1.00]$ from Mieske et al. (2006) for dwarf blue galaxies, while the line on the red side is $I$-band SBF Mag = $-1.68 + 4.5 \times [(V - I) - 1.15]$ from Tonry et al. (2000) for massive red galaxies. It is worth mentioning here that we use the observational fiducial lines merely as a “sanity check.” As we mentioned in Section 2, we do not consider the stochastic nature of the TP-AGB in this study. Therefore, we want to make it clear that our aim in this study is the blunt investigation of the effects of $\alpha$-element enhancement and the TP-AGB stars on the SBF magnitudes and broadband colors of simple stellar populations.

Compared to our earlier results (Lee et al. 2007a), the differences between the solar-scaled and the $\alpha$-enhanced models are smaller mainly because of the Teramo BaSTI isochrones updates (due to the low temperature opacities by Ferguson et al. 2005 for the $\alpha$-enhanced stellar models). At solar metallicity ($Z = 0.02$, filled squares), it is found from Figure 4 (also from Table 3) that the $\alpha$-enhanced models become about 0.02 mag redder and 0.35 mag brighter in this integrated $V - I$ versus $I$-band SBF magnitude plane compared to the solar-scaled ones mostly because of the oxygen enhancement as we noted in Figures 2 and 3. The right panel of Figure 4 displays the integrated $V - I$ colors versus $I$-band SBF magnitudes when the TP-AGBs are not included in the calculations. The general trend of the $\alpha$-enhanced models at solar metallicity ($Z = 0.02$, filled squares) becoming redder and brighter compared to the solar-scaled ones for $t \geq 1$ Gyr is mostly intact. It is seen, however, that the $I$-band SBF magnitudes are much too faint without the TP-AGBs to match the observations, especially at the metal-poor end.

Figure 5 is similar to Figure 2, but here displays the comparison of the sss and the aes Teramo BaSTI isochrones in $V - I$ versus $I$ CMDs at $Z = 0.0003$. It is important to note here that compared to Figure 2, the $V - I$ colors and the $I$-band magnitudes are hardly changed with the $\alpha$-enhancement on this very metal-poor side even at the upper RGB. It explains the comparatively smaller effects of $\alpha$-enhancement on SBF models and broadband colors.

integrated broadband colors at $Z = 0.0003$ in Figure 4. It is also interesting to see from the left panels (upper: without post-RGB; lower: with post-RGB but without TP-AGB) that the blue horizontal branch of 13 Gyr overlaps in $V-I$ color and $I$-band magnitude with the MS turnover of 1 Gyr here at $Z = 0.0003$. Note that compared to Figure 2, the $V-I$ colors and the $I$-band magnitudes are hardly changed with the $\alpha$-enhancement at this very metal-poor regime even at the upper RGB. It explains the comparably smaller effects of $\alpha$-enhancement at $Z = 0.0003$ in Figure 4. Also, note from the right panel that at all ages, the TP-AGBs go far redder and brighter compared to their RGB tips, particularly at this very metal-poor regime, which explains the importance of the TP-AGBs at $Z = 0.0003$ shown in Figure 4.

(A color version of this figure is available in the online journal.)

Figure 6. Similar to the left panel of Figure 4, but here $\alpha$-enhanced $I$-band SBF magnitudes as a function of $V-I$ are compared employing the Teramo BaSTI aes (dashed lines; without convective core overshooting) and aeo (solid lines; with convective core overshooting) isochrones at three given ages. The observational fiducial lines are same as in Figure 4. Note that at 1 Gyr and solar metallicity ($Z = 0.02$, filled squares), overshooting effects make the integrated $V-I$ colors bluer and the $I$-band SBF magnitudes fainter as indicated with an arrow. At 5 Gyr, however, the overshooting effects become minimal.

(A color version of this figure is available in the online journal.)

3.1. Comparison with Earlier Models

Figures 8 and 9 compare our scaled-solar (sss) models with other recent models available in the literature. Figure 8 contrasts our models based on the Teramo BaSTI “sss” isochrones with Raimondo et al. (2005), while Figure 9 does that with Martin-Franch & Aparicio (2006). The large filled symbols are used to indicate the solar metallicity in order to guide the eye. Both Figures 8 and 9 demonstrate that there are significant differences among models mostly because of the different treatment of the TP-AGB stars. Hence, we have collected several other available models in the literature and listed them in Table 2. We have only listed their integrated $V-I$ colors and $I$-band SBF magnitudes at 5 and 13 Gyr at solar metallicity.

Table 2 tells that there are non-negligible disparities among models at the same age and metallicity. The two different Worthey (1994) models\(^{10}\) evidently show that the different input

\(^{9}\) Among three different models in Martin-Franch & Aparicio (2006), we show the one with Pietrinferni et al. (2004) isochrones.

\(^{10}\) http://astro.wsu.edu/worthy/dial/dial_a_model.html
are compared with the Teramo SPoT models (Raimondo et al. 2005, hereafter R05) at 1, 5, and 13 Gyr for five different metallicities. To guide the eye, solar overshooting effects on the integrated models (1) are hotter at the upper MS compared to the aeo models and (2) do not go all the way to the RGB tip at 1 Gyr. They become virtually identical at 5 Gyr.

The overshooting effects on the integrated $V-I$ colors and the $I$-band SBF magnitudes that we described in Figure 6 can be understood from this CMD (see the text).

(A color version of this figure is available in the online journal.)

**Figure 7.** Similar to the right panels of Figures 1 and 2, but the aeo (dashed lines; without convective core overshooting) and the aeo (solid lines; with convective core overshooting) Teramo BaSTI isochrones are compared in the HRDs (left panels) and CMDs (right panels) at 1 and 5 Gyr at $Z = 0.02$. RGB tips are denoted with triangles for the aeo and circles for the aeo, respectively. Bottom panels show the details in the giant branches. It is interesting to note that the aeo models (1) are hotter at the upper MS compared to the aeo models and (2) do not go all the way to the RGB tip at 1 Gyr. They become virtually identical at 5 Gyr.

The overshooting effects on the integrated $V-I$ colors and the $I$-band SBF magnitudes that we described in Figure 6 can be understood from this CMD (see the text).

(A color version of this figure is available in the online journal.)

**Figure 8.** Similar to the left panel of Figure 4, but here our solar-scaled (ss; without convective core overshooting) $I$-band SBF models as a function of $V-I$ are compared with the Teramo SPoT models (Raimondo et al. 2005, hereafter R05) at 1, 5, and 13 Gyr for five different metallicities. To guide the eye, solar metallicity ($Z = 0.02$) is depicted with filled symbols.

(A color version of this figure is available in the online journal.)

**Figure 9.** Similar to Figure 8, but here our solar-scaled $I$-band SBF models as a function of $V-I$ are compared from that of Marín-Franch & Aparicio (2006, hereafter MA06) at 5, and 13 Gyr for five different metallicities. To guide the eye, solar metallicity ($Z = 0.02$) is depicted with filled symbols.

(A color version of this figure is available in the online journal.)

ingredients (i.e., isochrones) make significant (~0.1 mag in $V-I$ and ~0.55 mag in $I$-band SBF magnitudes) disparities at the same age and metallicity. Obviously, depending upon the ingredients and recipe the modelers adopt such as (1) isochrones, particularly the late-evolutionary stage evolutionary tracks such as RGB, AGB, and TP-AGB, (2) mass-loss scheme such as $\eta$ in Reimers (1975), (3) stellar library to convert the temperature and luminosity to colors and magnitudes, and (4) the IMF, one can get significantly different model outputs. It is therefore considerably important to carefully study the ingredients and recipe of different models before use. A rigorous test of the integrated photometric models is imperative.

On a positive note, however, our models agree extremely well with other recent works using independent stellar population models. For example, our scaled-solar (ss) models and Percival et al. (2009, hereafter P09) that are based upon the most up-to-date Teramo BaSTI with $\eta = 0.4$ and Salpeter IMF agree each other within 0.003 mag in $V-I$. Moreover, our scaled-solar models that are based upon the most up-to-date Padova isochrones with Salpeter IMF and Padova SSP models11 (Marigo et al. 2008) agree each other within 0.002 mag in $V-I$ at solar metallicity at 13 Gyr. Our models based upon the different isochrones will be compared with one another in detail in the following section.

### 3.2. Comparison of Padova and Teramo/BaSTI Solar-scaled SBF Models

Having discovered the non-negligible impacts of the input ingredients (i.e., isochrones) on the SBF magnitudes and broadband colors, here we calculate those quantities by employing stellar models from different groups but at the same solar-scaled

---

11 They are available from http://stev.oapd.inaf.it/cgi-bin/cmd.
composition. In this study, we contrast the widely used two stellar models, the Padova\textsuperscript{12} and the Teramo BaSTI stellar models\textsuperscript{13} at the same solar-scaled chemical composition. It is worth reiterating that α-enhanced stellar models could be even more diverse than expected because of differing definitions of “α-element.”

Figure 10 is similar to Figure 4, but here we contrast the I-band SBF models as a function of integrated \( V-I \) colors at given ages and metallicities using two different stellar models but at the same solar-scaled chemical composition with convective core overshooting. One is using the Teramo BaSTI (solid lines), and the other is using the Padova (dashed lines) stellar models. We employ their latest stellar models, which we directly download from their Web sites (see footnotes 1 and 9, respectively) in order to calculate the SBF predictions. We have employed the “sss” (solar-scaled with convective core overshooting) Teramo BaSTI models because we note that the Padova stellar models employ the convective core overshoot as the default in their models.\textsuperscript{14}

To guide the eye, solar metallicity models of varying ages are marked with filled squares. The two sets of stellar models result in significant disparities. In general, integrated \( V-I \) colors based on the Padova isochrones are comparatively redder than that from the Teramo BaSTI (see Table 3). It is also noted from the left panel that the I-band SBF magnitudes based upon the Teramo BaSTI become much fainter (>1 mag) at younger ages (\( t < 5 \) Gyr) with \( Z \geq 0.0004 \) compared to Padova models. In order to ascertain whether the remarkable dissimilarities are mainly caused by the rather poorly understood bright TP-AGB stars, we display the same models without TP-AGBs in the right panel of Figure 10. The differences using two different stellar models persist even without the TP-AGBs, although they are much less compared to that with the TP-AGBs.

From Figure 10, however, it is evident that the inclusion of TP-AGB stages is indeed necessary in matching the observations, which are represented by the thick bent lines. The systematic redder integrated \( V-I \) colors using the Padova stellar models compared to that using the Teramo BaSTI ones can be understood from the fact that the Padova RGBs are systematically cooler and redder than the Teramo BaSTI ones, as illustrated in Figures 11 and 12. For a clearer understanding of the cause of the dissimilarities of the stellar population model I-band SBF predictions as well as the integrated \( V-I \) colors using the Padova and the Teramo BaSTI stellar models, we illustrate the comparison of the Padova and the Teramo BaSTI stellar models in the HRDs and the CMDs in the following figures.

Notes. (1) The negative numbers in Columns 2 and 3 indicate that the effects make the SBF magnitude brighter and vice versa. (2) The positive numbers in Column 4 indicate that the effects make the integrated \( V-I \) color redder and vice versa.

\[12\] http://stev.oapd.inaf.it/cgi-bin/cmd

\[13\] http://193.204.1.62/index.html

\[14\] Please refer to footnotes 1 and 9 for the detailed treatment of the convective core overshooting from each stellar model group.
The small RGB temperature differences may be ascribed to the uncertainties of the convection treatment in the RGB stars. From the right panels of Figure 11, it is also noted that at younger ages ($t < 5$ Gyr), the TP-AGBs go far cooler and brighter than their RGB tips.

Figure 12 displays the comparison of the Teramo BaSTI (solid lines) and the Padova (dashed lines) isochrones in $V - I$ versus $I$ CMDs. Symbols for the RGB tips are same as in Figure 11. It is noted that the Padova RGBs, especially at the older ages ($t \geq 5$ Gyr), are relatively redder than the Teramo BaSTI ones in these CMDs. From the right panels of Figure 12, it is seen that, in general, the Padova TP-AGBs models are more complex than the Teramo BaSTI TP-AGBs. It is further noted from the right panels of Figure 12 that there are discontinuities for the Padova stellar models at the onset of the TP-AGB stage caused by structural changes (see the text). (A color version of this figure is available in the online journal.)

3.3. Near-IR SBF Models

Having found that (1) there are significant differences in the $I$-band SBF model predictions using the Padova and the Teramo BaSTI models and (2) the inclusion of TP-AGBs is crucial to match the observations, we now extend our investigation to longer wavelengths, including near-IR SBF models where the effects of the TP-AGB stage are considerably more pronounced than in the optical.

Figure 13 is similar to the left panel of Figure 10, but here we contrast the $z_{850}$-band SBF models based on the Padova and Teramo BaSTI (solid lines) stellar models at given ages and metallicities. To guide the eye, solar metallicity is depicted with filled squares. The observational fiducial lines are same as in Figure 4. In general, $V - I$ colors employing the Padova isochrones are comparatively redder than that employing the Teramo BaSTI. It is noted from the left panel that the $I$-band SBF magnitudes based upon the Teramo BaSTI are more than 1 mag fainter at younger ages ($t < 5$ Gyr) with $Z > 0.004$ compared to that employing Padova stellar models. The model disparities based on the two different stellar models linger even without TP-AGBs as shown in the right panel. It is evident though that the inclusion of TP-AGB stages is crucial to match the observations, which are the bent thick lines.

(A color version of this figure is available in the online journal.)
stellar models\textsuperscript{15} as a function of integrated $g_{475} - z_{850}$ colors at given ages and metallicities. The thick curved line is an empirical relation from Blakeslee et al. (2009). The arrows at 5, 8, and 13 Gyr indicate the estimated 0.4 dex $\alpha$-enhancement effects (see the text).

(A color version of this figure is available in the online journal.)

\textsuperscript{15} The reason that we show the $z_{850}$-band SBF models only based on the Padova stellar models is because the $z_{850}$-band magnitude is not yet available from the BaSTI Web sites.

\textsuperscript{16} The F475W and F850LP are equivalent to $g_{475}$ and $z_{850}$ bands, respectively.

\textsuperscript{17} http://193.204.1.79:21075/models.html
problems in the evolution of bright stars relevant to population synthesis modeling.

The $I$-band SBF models explored here are slightly fainter than the observations at the red end ($V-I > 1.15$), as shown in Figure 4. A partial solution may come from the nonlinear behavior between galaxy colors in $g_{475} - z_{850}$ and the $z_{850}$-band SBF magnitudes as illuminated by Blakeslee et al. (2009) in the sense that the red-end galaxies become rapidly fainter in $z_{850}$-band SBF magnitudes. In this context, the $\alpha$-enhanced SBF models help to reconcile the disagreement by making the theoretical $I$-band and $z$-band SBF brighter. Also, rigorous statistical investigations of model isochrones with TP-AGBs that are poorly populated yet very salient because of their prominent luminosity should help alleviate the discrepancies between the observations and the theoretical predictions as suggested by Cerviño et al. (2008), Raimondo (2009), and Gonzalez-Lopezlira et al. (2009). It is evident from the smaller scatter in the observations compared to the theoretical predictions that there is generally less variation among the AGB phases in actual galaxies than may be expected based on the models. The observed relations between SBF magnitudes and integrated colors are very tight, at least for evolved galaxies. The future sophisticated $\alpha$-enhanced SBF studies in various bandpasses should provide some additional constraints on the fine details of the calibration.

We thank Michele Cantiello, Santi Cassisi, Aaron Dotter, Leo Girardi, Paola Marigo, Reynier Peletier, and Gabriella Raimondo for very insightful discussions. We are also grateful to the anonymous referee for her/his careful reading and thoughtful comments that have improved our presentation. Support for this work was provided by the NSF through grant AST-0307487, the New Standard Stellar Population Models (NSSPM) project, and by NASA through grant HST-GO-11083.

fainter in $z$-band SBF causing the nonlinear relation between SBF magnitudes and the integrated colors as we have seen in Figure 13.

4. SUMMARY AND DISCUSSION

We have presented for the first time the effects of $\alpha$-element enhancement on SBF models and have compared these models with observations. For this purpose, we have employed the Teramo BaSTI isochrones in this study. In general, we find that the $\alpha$-element-enhanced $I$-band SBF magnitudes are about 0.35 mag brighter and their integrated $V - I$ colors are about 0.02 mag redder mostly because of the oxygen-enhancement effects on the upper RGBs and AGBs. Moreover, the importance of the TP-AGB stages for the $I$-band and near-IR band SBF magnitudes is illustrated and it becomes clear that TP-AGBs are the indispensable component in order to match the theoretical predictions with the observations. It is also noted that the TP-AGBs are more important in the metal-poor regime as shown in Figures 4, 5, 10, and 14.

We have further shown that the disparity in the SBF model and integrated $V - I$ color predictions is non-negligible when different stellar models are employed as input ingredients even at the same solar-scaled chemical composition. It is our understanding that what causes the disagreement in the integrated $V - I$ colors and $I$-band SBF models using different stellar models are (1) giant branch temperature differences, which occur depending upon the treatment of convection and (2) dissimilar stellar model atmospheres that are employed in order to convert from theoretical planes to observables. Further comparison of SBF model predictions with multi-band observations can help illuminate many of the remaining
