111102-2
We report on an all-sky search with the LIGO detectors for periodic gravitational waves in the frequency range 50–1100 Hz and with the frequency’s time derivative in the range $-5 \times 10^{-9}$–0 Hz s$^{-1}$. Data from the first eight months of the fifth LIGO science run (S5) have been used in this search, which is based on a semicoherent method (PowerFlux) of summing strain power. Observing no evidence of periodic gravitational radiation, we report 95% confidence-level upper limits on radiation emitted by any unknown isolated rotating neutron stars within the search range. Strain limits below $10^{-24}$ are obtained over a 200-Hz band, and the sensitivity improvement over previous searches increases the spatial volume sampled by an average factor of about 100 over the entire search band. For a neutron star with nominal equatorial ellipticity of $10^{-6}$, the search is sensitive to distances as great as 500 pc.

**Introduction.**—We have carried out an all-sky search with the Laser Interferometer Gravitational-Wave Observatory (LIGO) detectors [1,2] for periodic gravitational waves, using data from the first eight months of LIGO’s fifth science run (S5). We have searched over the frequency range 50–1100 Hz, allowing for a frequency time derivative in the range $-5 \times 10^{-9}$–0 Hz s$^{-1}$. These parameter ranges correspond to a minimum spin-down time scale $f/[4f]$ (the gravitational-wave spin-down age) of 80 yr for a source emitting at 50 Hz and 1750 yr for a source at 1100 Hz. Rotating neutron stars in our Galaxy are the prime target. At signal frequencies near 100 Hz we obtain strain sensitivities below $10^{-24}$, a strain at which one might optimistically expect to see the strongest signal from a previously unknown neutron star according to a generic argument originally made by Blandford [3], and extended in our previous search for such objects in S2 data [4]. A recent refinement of the argument [5] gives less optimistic estimates, but these too are surpassed by the experimental results presented here.

Using data from earlier science runs, the LIGO Scientific Collaboration has previously reported on all-sky searches for unknown rotating neutron stars (henceforth designated as “pulsars”). These searches have been performed using a short-period coherent search in the 160.0–728.8 Hz frequency range [4], and using a long-period semicoherent search in the 200–400 Hz frequency range in the S2 data [6] and the 50–1000 Hz range in the S4 data [7]. Einstein@Home, a distributed home computing effort [8], has also been running searches using a coherent first stage, followed by a simple coincidence stage, for which S3 and S4 results have been released [9,10]. The data collected in the S5 data run were more sensitive than in previous data runs, and the amount of data used here is an increase by a factor of 8 over that reported from the S4 data run [7], resulting in upper limits on periodic gravitational waves about a factor of 3–6 lower than those from the S4 data, depending on source frequency. This improvement gives an increase in sampled galactic volume by about a factor of 100, depending on the assumed source frequency and spin-down. At a signal frequency of 1100 Hz we achieve sensitivity to neutron stars of equatorial ellipticity $\epsilon \sim 10^{-6}$ at distances up to 500 pc (see [7] for relations). This ellipticity is at the upper end of the range thought to be sustainable by conventional neutron stars [11] and orders of magnitude below the maximum sustainable by a strange quark star [12]. The number of undiscovered, electromagnetically quiet neutron stars within 500 pc can be estimated to be $O(10^4–10^5)$ from the neutron star birth rate [13], although it is likely that only a tiny fraction would both be rotating fast enough to be accessible to LIGO [14] and remain in the local volume over the age of the Galaxy [15]. Only $\sim 25$ radio or x-ray pulsars have been discovered so far within that volume [16].

**LIGO detectors and the S5 science run.**—The LIGO detector network consists of a 4-km interferometer in Livingston, Louisiana, (L1), and two interferometers in Hanford, Washington, one 4 km and the other 2 km (H1 and H2).
The data analyzed in this Letter were produced in the first eight months of LIGO’s fifth science run. This run started at 16:00 UTC on November 4, 2005, at the LIGO-Hanford Observatory and at 16:00 UTC on November 14, 2005, at the LIGO-Livingston Observatory; the run ended at 00:00 UTC on October 1, 2007. During this run, all three LIGO detectors had displacement spectral amplitudes very near their design goals of $1.1 \times 10^{-19}$ m Hz$^{-1/2}$ [17] in their most sensitive frequency band near 150 Hz. (In terms of gravitational-wave strain, the H2 interferometer was roughly a factor of 2 less sensitive than the other two; its data were not used in this search.) Because of a variety of technical computing issues, a search over the full S5 data set (~2 yr) using the current PowerFlux program described below is impractical. Extensive revamping of the program is underway; results of the final ensuing search will be reported in the future.

The data were acquired and digitized at a rate of 16384 Hz. Data acquisition was periodically interrupted by disturbances such as seismic transients (natural or anthropogenic), reducing the net running time of the interferometers. In addition, there were 1–2 week commissioning breaks to repair equipment and address newly identified noise sources. The resulting duty factors for the interferometers were approximately 69% for H1, 77% for H2, and 57% for L1 during the first eight months. A nearby construction project degraded the L1 duty factor significantly during this early period of the S5 run. By the end of the S5 run, the cumulative duty factors had improved to 78% for H1, 79% for H2, and 66% for L1. For this search, approximately 4077 h of H1 data and 3070 h of L1 data were used, where each data segment used was required to contain at least 30 min of continuous interferometer operation.

**Signal waveforms.**—The general form of a gravitational-wave signal is described in terms of two orthogonal transverse polarizations defined to be ‘+’ with waveform $h_+(t)$ and ‘×’ with waveform $h_\times(t)$, for which separate and time-dependent antenna pattern factors $F_+$ and $F_\times$ apply, which depend on a polarization angle $\psi$ [18]. For periodic gravitational waves, which in general are elliptically polarized, the individual components $h_{+,\times}$ have the form $h_+(t) = A_+ \cos \Phi(t)$ and $h_\times(t) = A_\times \sin \Phi(t)$, where $A_+$ and $A_\times$ are the amplitudes of the two polarizations, and $\Phi(t)$ is the phase of the signal at the detector. For the semicoherent method used in this search, only the instantaneous signal frequency in the detector reference frame, $2\pi f(t) = d\Phi(t)/dt$, needs to be calculated. For an isolated, precession-free, rigidly rotating neutron star the quadrupolar amplitudes $A_+$ and $A_\times$ are related to wave amplitude, $h_0$, by $A_+ = h_0 [(1 + \cos^2 \iota)/2]$ and $A_\times = h_0 \cos \iota$, where $\iota$ describes the inclination angle of the star’s spin axis with respect to the line of sight. For such a star, the signal wave frequency $f$ is twice the rotation frequency $f_\nu$.

The detector reference frame frequency $f(t)$ can, to a very good approximation, be related to the frequency $\dot{f}(t)$ in the solar system barycenter (SSB) frame by [6] $\dot{f}(t) = \dot{\phi}(t) \frac{\cos \iota}{c}$, where $\dot{\phi}$ is the detector’s velocity with respect to the SSB frame, and $\mathbf{n}$ is the unit vector pointing from the detector toward the sky location of the source [6].

**Analysis method.**—The PowerFlux method used in this analysis is described in detail elsewhere [7] and is a variation upon the StackSlide method [19]. Here we summarize briefly its main features.

A strain power estimator is derived from summing measures of strain power from many short, 50% overlap, Hann-windowed Fourier transforms (SFTs) that have been created from 30-min intervals of calibrated strain data. In searching a narrow frequency range (0.5 mHz spacing) for an assumed source sky location, explicit corrections are made for Doppler modulations of the apparent source frequency. These modulations are due to the Earth’s rotation and its orbital motion around the SSB, and the frequency’s time derivative $\dot{f}$ intrinsic to the source. Corrections are also applied for antenna pattern modulation, assuming five different polarizations: four linear polarizations separated by $\pi/8$ in polarization angle and circular polarization. When summing, the variability of the noise is taken into account with a SFT-dependent weight proportional to the expected inverse variance of the background noise power (see [7,20] for detailed formulas).

The search range for initial frequency $f_0$ values is 50–1100 Hz with a uniform grid spacing equal to the size of a SFT frequency bin [1/(30 min)]. The range of $f$ values searched is $-5 \times 10^{-9}$–0 Hz s$^{-1}$ with a spacing of $5 \times 10^{-10}$ Hz s$^{-1}$, since isolated rotating neutron stars are generally expected to spin down with time. As discussed in our previous reports [4,6,7], the number of sky points that must be searched grows quadratically with the frequency $f_0$, ranging here from about 5000 at 50 Hz to about $2.4 \times 10^6$ at 1100 Hz. The sky grid used here is isotropic and covers the entire sky.

As described in [7], upper limits are computed from the highest-strain signal estimator over the entire sky for each 0.25-Hz band. Upper limits calculated in this method are strict frequentist limits on linear and circular polarization in small patches on the sky, with the limits quoted here being the highest limits in each 0.25-Hz band over broad regions of the sky. These are interpreted as limits on worst-case (linear polarization) and best-case (circular polarization) orientations of rotating neutron stars. Since the eight months of data analyzed here cover a large span of the Earth’s orbit, providing substantial Doppler modulation of source frequency, contamination from stationary instrumental lines is much reduced from earlier and shorter data runs. A total of only 0.6% of the search volume in sky location and spin-down had to be excluded from the upper-limit analysis because of Doppler stationarity.
The primary changes in the PowerFlux algorithm used in this search concern follow up of outlier candidates. (The general method for setting upper limits is identical to that used in the S4 search [7].) Here we summarize the follow-up method used. Single-interferometer searches are carried out separately for the H1 and L1 interferometers, leading to the upper limits on strain shown in Fig. 1 and discussed below. During determination of the maximum upper limit per sky region, per frequency band, and per spin-down step, a “domain map” is constructed of local signal-to-noise ratio (SNR) maxima, with the domains ordered by maximum grid point SNR and clustered if close in direction and frequency. The 1000 domains with the highest maximum SNR are then reanalyzed to obtain improved estimates of the associated candidate parameters, using a modified gradient search with a matched filter to maximize SNR with respect to source frequency, spin-down, sky location, polarization angle $\psi$, and inclination angle $\iota$ [20]. This maximization step samples frequency and spin-down much more finely than in the initial search.

When all sky regions and all spin-downs have been searched for a given 0.25 Hz band for both the H1 and L1 interferometers, the search pipeline outputs are compared, and the following criteria are used to define candidates for follow-up analysis. The H1 and L1 candidates must each have a SNR value greater than 6.25, and they must agree in frequency to within 1/180 Hz = 5.56 mHz, in spin-down to within $4 \times 10^{-10}$ Hz s$^{-1}$, and in sky location to within 0.14 rad. These conservative choices have been guided by simulated single-interferometer pulsar injections. Coincidence candidates within 0.1 Hz of one another are grouped together, since most candidates arise from detector spectral artifacts that become apparent upon manual investigation.

Candidates passing these criteria are subjected to a computationally intensive follow-up analysis that reproduces the all-sky PowerFlux search in a 0.25 Hz band around each candidate, this time using the (incoherently) combined strain powers from both interferometers. Sky maps of strain and SNR are created and examined manually for each individual interferometer and for the combined interferometers. Spectral estimates from noise decomposition are also examined to identify possible artifacts leading to the coincident outliers.

Results.—Figure 1 shows the lower of the H1 and L1 95% confidence-level upper limits on pulsar gravitational-wave amplitude $h_0$ for worst-case and best-case pulsar orientations for different declination bands (each with different run-averaged antenna pattern sensitivity). As in the S4 analysis, narrow frequency bands centered on the harmonics of the 60-Hz power mains, along with bands characterized by non-Gaussian noise, have been excluded from the displayed limits. Numerical values for frequencies and limits displayed in these figures can be obtained separately [21]. Systematic uncertainties on these values are dominated by calibration uncertainty at the $\sim$10% level.

All outliers were checked for coincidence between H1 and L1 interferometers, as described above. In most cases single-interferometer spectral artifacts were readily found upon initial inspection, most of which had known instrumental or environmental sources, such as mechanical resonances (“violin modes”) of the wires supporting interferometer mirrors, and power-mains harmonics of 60 Hz. Other outliers were tracked down to previously unknown electromagnetic disturbances. For six coincidence candidates, all at frequencies above 850 Hz, no instrumental spectral artifacts were apparent.

None of these six candidates were confirmed, however, as a detection of a constant-amplitude, constant-spin-down periodic source of gravitational radiation. In each case, we found that the combined H1-L1 SNR did not increase by more than 0.6 (0.4) units over the minimum (maximum) of the single-interferometer SNR’s, with four candidates showing a decrease for combined SNR. To understand the expectation for a true signal, we carried out a posteriori software signal injections, which indicated that combined SNR should typically show an increase over minimum SNR by more than 2.0 units for a single-interferometer SNR threshold of 6.25. Hence we conservatively veto all candidates with a SNR increase less than 1 unit. In addition, manual exploration of these candidates was carried out, using larger portions of the S5 run’s data, to determine whether SNR increased with additional data, and with subsets of the original eight-month data, to de-

FIG. 1 (color). Minimum (H1 or L1) upper limits (95% C.L.) on pulsar gravitational-wave amplitude $h_0$ for the equatorial (red), intermediate (green), and polar (blue) declination bands for best-case (lower curves) and worst-case (upper curves) pulsar orientations. Shown are all the minimum limits for each of the 11 spin-down values from $-5 \times 10^{-9}$ Hz s$^{-1}$ to zero in steps of $5 \times 10^{-10}$ Hz s$^{-1}$.
termine whether a transient astrophysical source could explain the candidate. None of these explorations proved fruitful. It should be noted that this opportunistic search for a coincidence detection does not affect the upper limits shown in Fig. 1. Also, because of large variation in average antenna pattern sensitivity with respect to source declination, the high-SNR coincidence candidates do not, in general, coincide with the outliers that define those upper limits.

We also note that multi-interferometer injections indicate that for signal frequencies above 850 Hz, the coincidence requirements in frequency and sky location could be tightened by a factor of 5 to 1 mHz and by a factor of 7 to 0.02 rad, respectively, with only a slight reduction in efficiency for true signals. None of the six candidates mentioned above satisfy these tighter criteria.

In summary, we have set strict, all-sky frequentist upper limits on the strength of continuous-wave gravitational radiation of linear and circular polarization, corresponding to least favorable and most favorable pulsar orientations, respectively. Follow-up analysis of coincidence candidates with SNR > 6.25 did not yield a detection. The limits on detected strain can be translated into limits on equatorial ellipticity as small as $10^{-6}$ for unknown neutron stars as far away as 500 pc. This ellipticity is at the upper end of the range thought to be sustainable by conventional neutron stars and orders of magnitude below the maximum sustainable by a strange quark star. Our limits on strain amplitude lie below (are more stringent than) the highest values in recent population simulations [5]. In the context of these models, our observational results imply that the galactic population of neutron stars spinning down primarily due to gravitational radiation approximately satisfies one or more of the following conditions: birth rate less than one per 30 yr, typical ellipticity less than $10^{-6}$, or typical spin period greater than 10 ms.

We thank Deepo Chakrabarty and David Kaplan for useful discussions. The authors gratefully acknowledge the support of the U.S. National Science Foundation for the construction and operation of the LIGO Laboratory and the Science and Technology Facilities Council of the U.K., the Max Planck Society, and the State of Niedersachsen, Germany, for support of the construction and operation of the GEO600 detector.
