ABSTRACT

Castillo, Alexandria, Photocatalytic Degradation of Simazine Under Visible Light Using Zinc Oxide/Molybdenum Disulfide Heterostructures. Master of Science (MS), December, 2019, 56 pp, 13 figures, 5 tables, 46 references, 38 titles.

The photocatalytic degradation of simazine under visible light by using ZnO/MoS₂ heterostructures was investigated. Reaction parameters studied to optimize simazine degradation included pH, loading mass of the photocatalyst, and percentage of MoS₂ in the heterostructure. pH 2 was the optimal environment for the degradation reaction of all catalysts. A loading mass of 20 mg for each of the ZnO/MoS₂ photocatalysts was determined to be the most effective for in the degradation process. The degradation reactions were observed to follow 2nd order kinetics for all photocatalysts at all temperatures. Band gap studies confirmed a lower energy than that of pure ZnO for all synthesized photocatalysts.

DEDICATION

Without the love and support of my parents, David and Maria Castillo, the completion of my master studies would not have been possible. In addition, I would like to thank Javier Cantu for the love and patience that motivated me to continue pushing forward and finish this degree. There are not enough words to express my love and gratitude for you all.

ACKNOWLEDGMENTS

I would like to thank Dr. J. G. Parsons, chair of my thesis committee, for the time and effort he invested in me. Without his mentorship the completion of my master's degree would not have been possible. Thanks to his encouragement to continue my education I would not have had the courage to continue with doctoral studies. To my thesis committee members: thank you for the support and guidance that helped me accomplish this part of my educational career.

To my lab mates Kenneth Flores, Daniel Ramirez, Joe Lara, Rick Luna, Alexis Echeverria, John Paul Valle, and Valeria Velasquez: thank you for your friendship and support, without you, the countless hours spent in the research lab would have not been so worthwhile.

CHAPTER I

BACKGROUND

Simazine Mode of Action & Regulated Use

Simazine is a symmetrical chloro-s-triazine herbicide. It is primarily utilized for the control of broad leaf weeds and annual grasses in agricultural, non-agricultural settings, as an algicide in fish farm ponds, algicide in water towers, and as an algicide aquariums.¹ Simazine is effectively distributed throughout the weed, however it can primarily be found in the leaves.² In annual grasses and broad leaf weeds, simazine inhibits the photosynthetic electron transport process in the leaves. Photosynthesis occurs in the chloroplasts of plants; the chloroplasts inner membranes are organized into sacs called thylakoids. In the thylakoids, after a photon of light excites the photosystem, the main electron acceptor plastoquinone is reduced and starts a chain reaction of enzyme catalyzed events that generate ATP and NADPH. When simazine is present, it binds to plastoquinone, preventing the photosynthetic electron transport process, stopping CO₂ fixation and the production of ATP and NADPH.³ The weed plants can no longer survive due to their inability to reoxidize plastoquinone thus making simazine an effective herbicide.

Pesticides and herbicides are frequently employed in agriculture to increase crop yield. However, over application has led to the leaching of these organic pollutants into water supplies used as sources for drinking water. Concerns with the detection of increased concentrations of simazine in water sources around the world have led to regulations regarding its usage. Simazine is one of the most commonly detected herbicides in ground and surface water in the United

States.³⁻⁵ This is due to the fact that it is widely used for weed control in North and South America in various application such as vineyards, orchards, and forestry,⁷⁻⁹. Europe banned the use of simazine in the early 2000s.¹⁰ In the US in the Midwest, 90% of the 2 million pounds applied is to corn crops; in California, 90% of the 1 million pounds applied is to almonds, grapes, oranges, and walnuts; in Florida, 100% of the 1 million pounds applied is to citrus, including grapefruit and oranges.¹¹ The maximum containment level in drinking water has been set at 4.0 parts per billion. The regulation of simazine has come from the determination that it is an endocrine disrupting chemical.

Endocrine Disruption & Toxicity

Regulations have been enacted to protect the population from the potential risks of acute and chronic exposure to simazine. Endocrine disrupting chemicals, as the name suggests, interfere with the body's endocrine system. When an endocrine disruptor is present in the body it can interfere with the synthesis, transportation, binding, and/or action of natural hormones¹², therefore affecting the reproductive and developmental health of the organism. Triazine herbicides have been shown to directly affect the reproductive health of amphibians and rodents.^{13,14} A case study was performed on California farmers, predominately Hispanic, to help identify the risks of prostate cancer from exposure to pesticides. The case study concluded that the risk of developing prostate cancer increased with the increased exposure to simazine.¹⁵

The US EPA has categorized simazine in Toxicology Category III for dermal and inhalation routes of exposure and Toxicology Category IV for the oral exposure route. The median lethal dose for oral exposure is greater than 5g/kg, greater than 2g/kg for dermal exposure, and 1.71 mg/L for inhalation. In spite of the regulated use, simazine is still being found in many drinking water sources.

Degradation

Finding way to successfully eliminate the presence of toxic herbicides in our drinking water has become a very important environmental issue. The degradation of simazine by abiotic and biotic processes is dependent on physicochemical properties such as solubility and sorption capacity, which contribute to its movement into water systems. Simazine is slightly soluble in water (5.0 mg/L at 20°C) and weakly adsorbs to clays, mineral rich and sandy soils.¹ Therefore, these surfaces cannot retain simazine leading to the chemical leaching into water. On the other hand, simazine has a greater sorption capacity to soils containing organic matter.¹ The presence of organic matter in the soil limits the leaching of simazine.

Simazine has a variety of degradation pathways. Figure 1 depicts the major abiotic and biotic degradation pathways. Hydrolysis involves the production of 2-hydroxy-4,6-bis(ethylamino)-s-triazine (3b) from simazine (3a). Biotic oxidation and photolysis of simazine yields 2-chloro-4-amino-6-(ethylamino)-s-triazine (3c) and 2-chloro-4,6-diamino-s-triazine (3d). Abiotic degradation through photolysis is potentially a promising route for removing simazine. Photocatalytic degradation of s-triazines under ultra-violet radiation has been thoroughly studied.¹⁶ However, UV radiation only accounts for about 4% of natural sunlight. Under natural conditions simazine can persist in the environment for approximately 8 months.¹ Biotic degradation involves the presence of bacterial or fungal strains capable of dechlorinating the ring structure and hydrolyzing the ring, as well as dealkylating the amine side chains. Numerous microbial strains capable of degrading s-triazines have been identified¹⁷; however, degradation by biotic means is relatively slow.¹ Even though simazine is degradable naturally, its persistence in the soil and eventual leaching into our drinking water calls for the development of better methods to remove it from our drinking water.

Figure 1: Degradation pathways of simazine (a) to 2-hydroxy-4,6-bis(ethylamino)-s-triazine (b), 2-chloro-4-amino-6-(ethylamino)-s-triazine (c) 2-chloro-4,6-diamino-s-triazine (d)¹

CHAPTER II

INTRODUCTION

Photocatalysis

Photocatalysis is a process in which photons interact with a semiconducting material generating an electron-hole pair upon excitation of an electron. The excited electron is promoted from the lowest unoccupied molecular orbital, conductive band, to the highest occupied molecular orbital, valence band in the semiconducting material. The semiconducting material is considered a photocatalyst because it changes the rate of a chemical reaction when irradiated. The degradation of organic pollutants^{18,19}, and hydrogen production by water splitting²⁰, are just a few examples of the reactions of photocatalysts.

Photocatalysts are generally also known as semiconductors. For a material to be classified as a semiconductor it must have a band gap between 1.5 to 3.0 eV. Band gap refers to the energy difference between the conductive and valence band and is related to the energy required to excite an electron from the former to the latter. Materials can be divided into three categories according to their band gap which includes: conductors, semiconductors, and insulators. When a photocatalyst is exposed to a wavelength of light that is equal to or greater than the band gap energy, an electron promotion occurs and formation of an electron and electron hole pair creates two locations for photo-reduction and photo-oxidation processes to occur. Recombination of the electron with the electron hole can occur, however, the properties of semiconductors are designed to avoid the recombination process. In solutions, species

responsible for the potential redox processes are considered to be reactive oxygen species (ROS). Photocatalytic reactions involving advanced oxidative processes are dependent on the ROS generated by the photocatalyst.²¹

Generation of Reactive Oxygen Species

Photocatalytic reactions performed in an aqueous and aerobic environment will generate ROS simultaneously from the water and oxygen present. Figure 2 illustrates the generation of the four major ROS present in photocatalysis: superoxide anion radical ($\bullet\text{O}_2^-$), hydrogen peroxide (H_2O_2), singlet oxygen (^1O), and hydroxyl radical ($\bullet\text{OH}$). Photo-reduction occurs near the conductive band where the photoexcited electrons are promoted. Sequential photo-reduction of molecular oxygen produces a superoxide radical (1), which can be further reduced to a peroxide ion, O_2^{2-} (2). From the protonation of each two molecular orbitals hydrogen peroxide is generated (3). The hydrogen peroxide can be further reduced to also give the hydroxide radical after the dissociation of its O-O bond.

Photo-oxidation processes occur at the conductive band of the photocatalyst, the site of the electron holes. After the autoionization of water in which H_2O deprotonates to yield hydroxide ions, OH^- , and H^+ (4), the hydroxide ions are oxidized to hydroxyl radicals (5). The two-hole oxidation of water also yields hydrogen peroxide.

The generation of the four major ROS will dictate the efficiency of the semiconductor employed for the photocatalytic degradation of organic pollutants. Modification of photocatalysts is needed sometimes to increase ROS generation and improve the overall efficiency of advanced oxidation reactions.

Figure 2: Reactive oxygen species generated from photo-oxidation and photo-reduction²¹

Modification of Photocatalysts

Metal oxides are the largest group of materials utilized as photocatalysts. However, most of the transition metal oxides have a large band gap, which limits their photoexcitation to the UV region. Although an obvious disadvantage, the generally high band gap energy of transition metal oxides can be modified a number of ways. These modifications are a way of tuning the electronic structure, therefore affecting the charge carrier mobility of the reactive oxygen species. In addition, modification helps prevent recombination of the excited electron with the hole in the valance band.

Semiconductors can be doped with metals or nonmetals, or a mixture of both. Doping with a metal, nonmetal, or a combination of both can reduce the band gap and shift the

responsiveness of the material to the visible light region. Metal dopants such as Co, Cr, and Zn for example can create a new band below the conductive band of the semiconductor.²² Doping with non-metals such as carbon, nitrogen, and sulphur can decrease the bandgap of wide band gap semiconductors into the visible light region by creating a new band above the valence band of the semiconductor.^{22,23} The presence of a metal or nonmetal dopant can help avoid the recombination of the excited electron with the electron hole therefore increasing the photocatalytic activity of the material.

Semiconductors with variable band gaps can be combined to form photocatalytic composites. A photocatalyst with a large band gap is normally paired to one with a narrower band gap, which electrons from the conductive band of the narrower band gap semiconductor transfer to the conductive band of the larger band gap semiconductor.^{24,25} Extensive research has been performed on composites containing ZnO due to its wide tunable band gap.²⁶

Sensitization is another method of modifying photocatalysts. Complexes with chromophores that absorb visible light such as dyes are attached to the semiconductor. When irradiated with visible light, the sensitizer will transfer their electrons to the conductive band of the photocatalyst. The method of sensitization is not as reliable for the degradation of organic pollutants. The sensitizer may be degraded along with the other organic compounds, as well extra steps in the synthesis of the photocatalyst need to be taken to prevent the degradation of the sensitizer.^{27,28}

ZnO

Zinc oxide is among the most studied metal oxides in photocatalysis alongside titanium dioxide. This is due to its large excitation binding of 60 mV and wide band gap of 3.37 eV. ZnO has been used for the photocatalytic degradation of dyes, and other persistent organic

pollutants.^{29,30} ZnO has three crystal structures: cubic rock-salt, cubic zinc-blende and hexagonal wurtzite (Figure 3). Hexagonal wurtzite is the most abundant and thermodynamically stable of the three.

The wide band gap of ZnO limits photocatalysis to the UV region. Therefore, modifications such as those mentioned earlier are necessary in order to enhance the photocatalytic activity of ZnO into the visible region. Ultimately, the goal of photocatalysis is to synthesis a material that will work affectively under natural sunlight. Zinc oxide continues to be a favorable candidate because its band gap is tunable. Doping with n-type metal ions, which act as electron donors, creates a level above the valance band of ZnO; while doping with p-type metal ions, which act as electron acceptors, creates a level below the conductive band of ZnO.³¹ Another popular modification of ZnO is the formation of nanocomposites with another semiconducting material such as TiO₂, SnO, graphene, CdS, and CuO.²⁶ While all nanocomposites exhibit different photocatalytic activity, the literature shows that ZnO can be enhanced and function in the visible range.

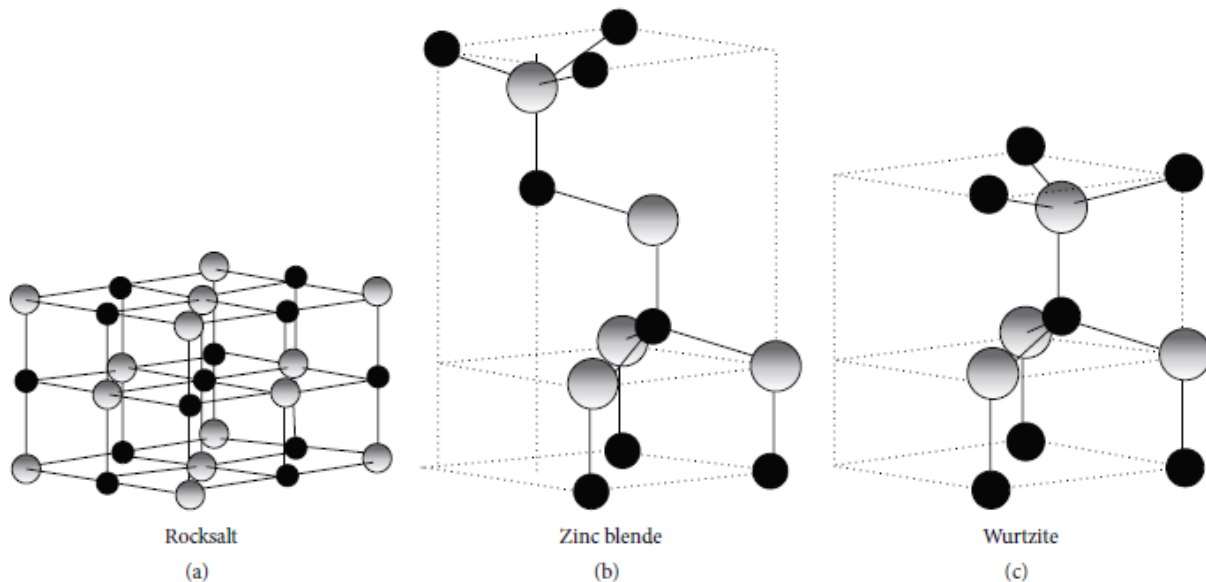

Figure 3: Three crystal structures of ZnO: rocksalt (a), zinc blende (b), and wurtzite (c)²⁶

MoS₂

Molybdenum disulfide is a transition metal dichalcogenide with a number of industrial application including hydrogen desulfurization and dry lubricants.³² MoS₂ is a nontoxic and naturally abundant material. The structure of bulk MoS₂ is comprised of S-Mo-S stacked layers held together by weak van-der-Waals interactions. There are four known polytypes of MoS₂: 1H, 1T, 2H, and 3R.³³ Three of the four polymorphs are shown in Figure 4. The number represents the stacking order of each layer while the letter denotes the crystallographic structure. In the 1H and 2H polytypes the central molybdenum atom is coordinated to six sulfur atoms creating a hexagonal structure. There are two repeating layers in 2H-MoS₂ and only one in 1H-MoS₂. It has been determined that 2H-MoS₂ is the most stable of the four polytypes. In the 1T polytype, the coordination of the sulfur atoms to the central molybdenum atom creates a trigonal structure. In the 3R-MoS₂ polytype three layers from a rhombohedral structure.

The many layers of bulk MoS₂ can be separated by means of chemical and mechanical exfoliation³⁴, therefore changing the electronic properties of MoS₂ as the number of layers decreases. By controlling the morphology and reducing the amount of layers the photocatalytic performance of this material can be improved. MoS₂ based photocatalysts have recently become of interest because of this discovery. MoS₂ has helped facilitate the photocatalytic generation of hydrogen from water splitting.^{35,36} The 1.2 eV indirect band gap of bulk molybdenum disulfide is too small to induce photocatalytic reactions. However, as the number of layers in the structure decrease, the band gap increases to 1.9 eV for single layer MoS₂ making it a feasible semiconductor for photocatalysis.^{37,38}

Figure 4: Top and lateral view of the crystal structures of 1T, 2H, and 3R polytypes²⁹

ZnO/MoS₂

A ZnO/MoS₂ composite shows great promise as a photocatalytic material. As previously mentioned, ZnO despite having a high electron carrier mobility is limited by its high recombination rate of electron-hole pairs, its wide band gap which restricts its absorption ability to the UV region.³⁹ The direct band gap of small layer MoS₂ and strong absorption in the visible region can enhance the photocatalytic activity of ZnO and help minimize the fast recombination of ZnO, while the high charge carrier mobility of ZnO compensates for the low charge carrier mobility of MoS₂.⁴⁰ ZnO/MoS₂ heterostructures have been proven to photocatalytically degrade organic dyes under visible light.^{41,42} Figure 4 illustrates the mechanism for the photocatalytic degradation of organic compounds by ZnO/MoS₂ composites under visible light. Upon irradiation, electrons in the valence band of both ZnO and MoS₂ are excited. The electrons from the conductive band in the MoS₂ are transferred to the lower conductive band of ZnO. Excited holes are simultaneously transferred from the valence band of ZnO to the higher MoS₂ valence

band. Photo-oxidation occurs at the valence band of MoS₂ while photo-reduction occurs at the conductive band of ZnO.

Figure 5: Proposed mechanism of organic pollutant degradation by ZnO/MoS₂ composites under visible light⁴

CHAPTER III

MATERIALS AND METHODS

Synthesis of ZnO/MoS₂

Four zinc oxide/molybdenum disulfide heterostructures were prepared and tested for their photocatalytic efficiency. ZnO/MoS₂ was synthesized by adding 200 mg (6% wt) of commercial molybdenum disulfide to 10 mL of Millipore water and sonicated in a blank for 3 hours. 2.0 g of hexamethylenetriamine and zinc nitrate hexahydrate were added to two separate beakers containing 40 mL of Millipore water and stirred for 30 minutes. After 30 minutes, the two respective solutions were mixed and stirred for 1 hour. The sonicated MoS₂ solution was added to the hexamethylenetriamine and zinc nitrate hexahydrate mixture. The solution was then pH adjusted to ~11 with 1M and 5M NaOH solutions. The solution was added to a Teflon lined stainless steel autoclave and placed in an oven at 140°C for 2 hours. The resulting material once cooled to room temperature was filtered and washed with Millipore water, methanol, and acetone. Separate solutions of 100 mg (3%) and 400 mg (12% wt) of MoS₂ were also prepared. A fourth photocatalyst, ZnO/MoS₂ (6% wt n/c) was prepared with 200 mg of noncommercial (n/c) MoS₂ synthesized in the laboratory.

Synthesis of MoS₂

To a 250 mL round bottom flask, 5 g of ammonium heptamolybdate tetrahydrate, 60 mL of ammonium sulfide, and 50 mL ammonium hydroxide were added. The mixture was refluxed at 70°C for 1 hour. The solution was cooled in an ice bath to crystallize, then filtrated and

washed with cold isopropanol. The resulting crystals were placed into a porcelain crucible, and heated to 450°C for 1 hour inside a Thermolyne tube furnace under constant flow of H₂/Ar (10%/90%) mixture.

XRD Characterization

All photocatalysts were characterized using a Bruker D2 Phaser X-Ray Diffractometer equipped with a cobalt x-ray source that emits x-rays at 1.79Å, and a Fe filter. Samples were analyzed from a 2θ angle of 10-80°, a 0.05° step size, and counting time step of 2 seconds. The diffraction pattern fittings were performed with Fullprof software and crystallographic structures from the literature.^{26,32}

Band Gap Determination

All photocatalysts were analyzed for band gap using a Perkin Elmer Lamda 950 UV-VIS-NIR Spectrophotometer. Measurements were recorded in %Reflectance from a range of 200-800 nm.

HPLC Analysis

The simazine samples from the degradation studies were analyzed using a Thermo ScientificUltimate 3000 High Performance Liquid Chromatograph (HPLC). The HPLC was equipped with a reverse phase C18 column and photodiode detector with UV-Vis lamps set to 220 and 225 nm. The mobile phase was comprised of 35/65 acetonitrile/acetate buffer (0.1M, pH 6) solution. 10 μL aliquots of each sample were injected into the column at a flow rate of 1 mL per minute, with a sample run time of 7 minutes.

Degradation Studies

Degradation studies were performed in a New Brunswick Scientific Innova 44 incubator under a 100W metal halide lamp. Degradation studies were performed for ZnO/MoS_{2-x} (x = 3%

wt, 6% wt, 12% wt) photocatalysts and MoS₂. Simazine samples were reacted with each photocatalyst in 10 mL beakers under the metal halide lamp for the desired amount of time and temperature under constant agitation. After each reaction, the samples were centrifuged for 5 minutes at 3500 rpm and the supernatants were decanted and analyzed. All reactions were performed using triplicate measurements for QA-QC and statistical purposes.

pH Study

All photocatalysts were tested over a pH range of 2 to 8. The reactions were performed using 25 ppm simazine solutions were pH adjusted. The pH adjustments were performed using either dilute HCl and or dilute NaOH solutions. 4 mL of pH adjusted simazine solution was added to 20 mg of photocatalyst and irradiated with visible light for 1 hour at 20°C.

Loading Study

The amount of photocatalytic material was varied from 10, 20, 40, and 80 mg to assess the optimal amount needed for simazine degradation. The reactions were performed at 20°C for 1 hour, with 4 ml aliquots of 25 ppm simazine at the optimal pH determined from the pH study.

Kinetics Study

To determine the degradation reaction kinetics 4 ml aliquots of 25 ppm simazine solutions at the optimal pH and photocatalyst loading mass were irradiated with visible light for 2 hours at 20, 30, and 50°C. As the photocatalytic reaction proceeded, 1.5 µL aliquots of each sample were taken for HPLC analysis.

Concentration Variance

The concentration of simazine was varied at 5 ppm, 15 ppm, and 25 pm. All three photocatalysts were reacted with 4 ml of simazine at each concentration, optimal pH and loading mass for 1 hour under visible light at 20°C. For 15 and 25 ppm samples, 1.5µL aliquots were

extracted every 15 minutes, centrifuged for 5 minutes at 3500 rpm, and analyzed. The 5 ppm samples, 1.5 μ L aliquots were taken every 5 minutes and analyzed. From the data, the Gibbs free energy, enthalpy, entropy and activation energy of the degradation reaction was calculated.

Table 1: Lattice parameters for all synthesized photocatalyst

Fitted diffraction patterns for all synthesized photocatalysts are shown in Figures 6-9. The solid line indicates the diffraction pattern for the sample while the larger dashed line indicates the diffraction fitting. The smaller dashed line indicates the difference between the diffraction pattern and fitting; and the vertical markings indicate the Bragg planes.

All ZnO/MoS₂ photocatalysts displayed a hexagonal crystal structure for the ZnO and MoS₂ phases present in the material, and lattice parameters consistent with literature values.^{26,32} A summarization of these parameters are shown in Table 1. ZnO conformed to the hexagonal wurtzite crystal structure with space group, P63/mc. The average values for the lattice parameters of each photocatalyst were $a = b = 3.25 \text{ \AA}$, and $c = 5.20 \text{ \AA}$. MoS₂ conformed to the 2H-MoS₂ polytype with space group, P63/mmc. The average lattice parameters of each photocatalyst were $a = b = 3.17 \text{ \AA}$, and $c = 12.26 \text{ \AA}$. The angles α, β , and γ were 90, 90, and 120, respectively.

The first major peak seen in all diffraction patterns corresponds to the (002) plane in MoS₂. The intensity of the diffraction peak increased as the mass percent of MoS₂ increased in the sample. There is a significant difference in the intensity of the (002) peak between ZnO/MoS₂ 6% and ZnO/MoS₂ 6% n/c. The decrease in intensity for the sample synthesized with

noncommercial MoS₂ is related to the number of layers of MoS₂ present, not the mass percent. There is less stacking in noncommercial MoS₂. The intensity of five major peaks at 37°, 40°, 42°, 55°, and 66° (2θ) from the ZnO crystal structure remained constant for all photocatalysts, as the concentration of ZnO remained constant. The (100) plane is represented by the diffraction peak at 37°. The (002) plane showed reflectance at 40°, and the (101) plane showed reflectance at 42°. At 55° and 66°, the (102) and (110) planes showed reflectance, respectively.

Figure 10: pH of simazine and corresponding degradation by ZnO/MoS₂ (3%, 6%, 12% wt), pure MoS₂, and ZnO/MoS₂ 6% wt n/c

The degradation of simazine over a 1 hour period and pH range of 2-8 was recorded in milligrams of simazine per gram of photocatalyst. The photocatalytic efficiency of ZnO/MoS₂

(3%, 6%, 6% n/c, and 12% wt MoS₂) and pure MoS₂ is displayed in Figure 5. At pH 2 the greatest amount of simazine degradation was observed. For all materials expect ZnO/MoS₂ 6% wt n/c, simazine degradation decreased from pH 2 to 4, increased from pH 4 to 6, then decreased again from pH 6 to 8. At pH 2, the simazine degradation was 3.044 mg/g for ZnO/MoS₂ 3% wt, 2.800 mg/g for ZnO/MoS₂ 6% wt, 2.871 mg/g for ZnO/MoS₂ 12% wt, 1.585 mg/g for pure commercial MoS₂, and 3.106 mg/g for ZnO/MoS₂ 6% wt n/c. At pH 4 the least amount of simazine degradation was 1.616 mg/g, 1.515 mg/g, and 1.936 mg/g respectively for ZnO/MoS₂ (3%, 6%, 12% wt). A decrease in simazine degradation from pH 2 to pH 8 occurred for ZnO/MoS₂ 6% wt n/c. When comparing the ZnO/MoS₂ 6% wt synthesized by commercial and non-commercial MoS₂, the mg/g of simazine degraded was greater with the ZnO/MoS₂ synthesized with non-commercial MoS₂. The amount degraded by the n/c photocatalyst is slightly greater than ZnO/MoS₂ 3% wt.

Introducing small amounts of MoS₂ to the ZnO structure has been shown to enhance the photocatalytic activity of ZnO.^{31, 39, 41} However, excess amounts of MoS₂ can potentially hinder degradation by obstructing the light absorption efficiency of the ZnO material.³⁹ Higher amounts of MoS₂ do not result in greater simazine degradation, which is further evident when comparing the pH study data for the 3 wt% and 12 wt%. There was higher simazine degradation was observed for the 3 wt% catalyst. Although simazine degradation with 12 wt% was slightly higher than for the 6 wt%, this can be explained by the possible the adsorption of simazine to the MoS₂. Photodegradation by MoS₂ alone resulted in less than 30% simazine removal.

The photocatalytic efficiency of the material can be dependent on the concentration of simazine in the solution. According to Ward *et al.*, the solubility of simazine decreases from 5.81(10⁻⁴ M) at pH 1 to 0.25(10⁻⁴ M) at pH 10.⁴³ Furthermore, the solubility of simazine is based on the 2-substituent and the alkyl groups located at the 4- and 6- positions. The trend in solubility

is similar to the trend in simazine degradation as pH increases. For reactions such as photocatalytic degradation involving the surface of semiconductors, pH plays a vital role in the surface charge properties of the semiconductor, which can affect photoredox processes.⁴⁴ For example, semiconducting materials generally are negatively charged will experience repulsion from negatively charged simazine in alkaline conditions.⁴⁵ In addition, H_2O_2 an important reactive oxygen species, is not stable in alkaline conditions and will not be able to perform carry out photo-oxidation.

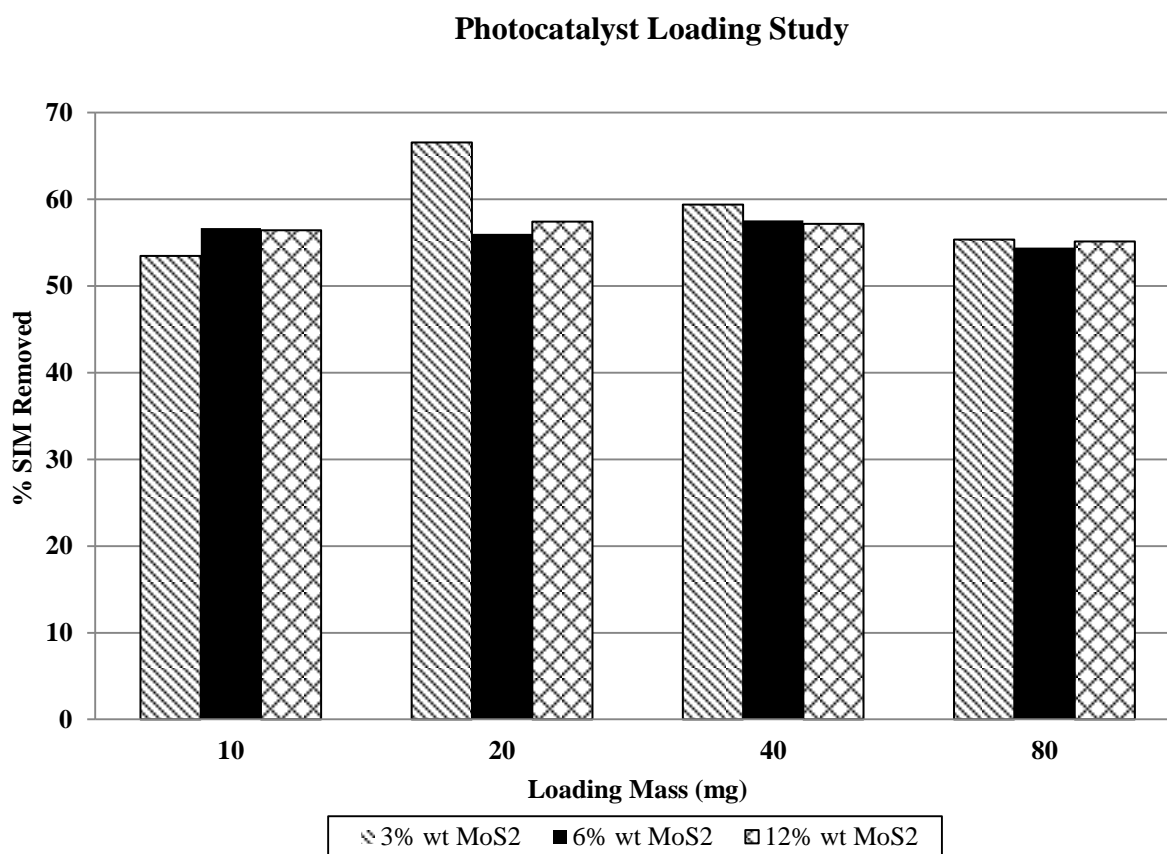

Figure 11: Percentage of simazine removed per milligram of ZnO/MoS₂ (3%, 6%, and 12% wt MoS₂)

The amount of photocatalyst present in the degradation reaction was varied from 10 to 80 milligrams for ZnO/MoS₂ (3%, 6%, and 12% wt MoS₂) at the optimal pH. The percentage of

simazine removed by each photocatalyst was observed to range from 50 to 70 percent as shown in Figure 7. For ZnO/MoS₂ 3% wt and ZnO/MoS₂ 12% wt, 20 mg of catalyst yielded 66.55% and 57.43% simazine degradation, respectively, an increase in removal compared to the 10 mg photocatalyst sample. There was approximately a 13% difference in the percent degradation between 10 mg and 20 mg of ZnO/MoS₂ 3% wt, and approximately 1% for ZnO/MoS₂ 12% wt. With both photocatalysts, the percent degradation was observed to slightly decrease at 40 mg and 80 mg. While 40 mg of ZnO/MoS₂ 6% wt removed 57.57% of simazine in the reaction, 10 mg removed 56.68%, and 20 mg removed 56.01%. The largest difference occurred between 40 mg and 80 mg, where 80 mg of ZnO/MoS₂ (6% wt) degraded 54.42%. Due to only slight differences in percent simazine degraded, 20 mg of photocatalyst were utilized for the following studies.

Degradation Kinetics

Figure12: Kinetic plot for ZnO/MoS₂ (3, 6, 6 n/c, 12%) at 20 °C

The degradation kinetics for a 1-hour reaction period at 20 °C by different ZnO/MoS₂ photocatalysts was determined by plotting the inverse of the concentration of simazine remaining as a function of time. The results are shown in Figure 8. The linear relationship between $\frac{1}{[SIM]}$ versus time indicated the degradation reaction occurred through 2nd order kinetics. The degradation at 30 and 50°C yielded similar results for all the photocatalysts studied. The slope of the 2nd order kinetics plot is equal to the rate constant for the reaction. Table 1 summarizes the determined rate constants and are expressed as L*mg⁻¹*sec⁻¹. For ZnO/MoS₂ (3, 6%) the highest rate of degradation was observed at 50°C. At 30°C the highest rate of degradation was observed for ZnO/MoS₂ (12%). When comparing the ZnO/MoS₂ (6%) synthesized by commercial and non-commercial MoS₂ the rate of degradation increased with the non-commercial MoS₂. When the temperature of the degradation reaction increased from 20 to 50°C the instantaneous rate, expressed as mg*L⁻¹*sec⁻¹, increased for the 3, 6, and 12% photocatalysts.

	20 °C	30 °C	50 °C
ZnO/MoS₂ 3%	6.93	6.27	7.61
ZnO/MoS₂ 6%	4.56	5.65	8.93
ZnO/MoS₂ 12%	4.00	7.45	6.12
ZnO/MoS₂ 6% n/c	6.69		

Table 2: Rate constants (10⁻⁴) (L*mg⁻¹*s⁻¹) for degradation by Zn/MoS₂ (3, 6, 12, 6% n/c) at 20, 30, & 50°C

	20 °C	30 °C	50 °C
ZnO/MoS₂ 3%	1.23	1.32	1.59
ZnO/MoS₂ 6%	0.697	1.07	1.75
ZnO/MoS₂ 12%	0.665	1.28	1.21
ZnO/MoS₂ 6% n/c	1.02		

Table 3: Instantaneous rates (10^{-3}) ($\text{mg}\cdot\text{L}^{-1}\cdot\text{s}^{-1}$) of degradation by Zn/MoS₂ (3, 6, 12, 6% n/c) at 20, 30, & 50°C

Concentration Variance

To examine the effects of simazine concentration on the rate of degradation, the concentration was varied from 5 to 25 ppm at 20°C. The relationship between initial simazine concentration and simazine degradation is shown in Figure 9. As the concentration of simazine decreased from 25 ppm to 15 ppm, the percentage of simazine degraded decreased from 60.3 to 48.4% for ZnO/MoS₂ 12% wt, 64.1 to 51.0% for ZnO/MoS₂ 6% wt, and 59.8 to 50.9% for ZnO/MoS₂ 3% wt. However, with the initial concentration of simazine was 5 ppm, there was 0% degradation for ZnO/MoS₂ (3, 12% wt), and only 3% degradation for ZnO/MoS₂ 6% wt. The concentration of simazine greatly affects the efficiency of photocatalytic degradation. However, when comparing the instantaneous rates of degradation at 20°C when there was 25 ppm of simazine versus 15 ppm of simazine present, the rates for the degradation of 15 ppm were greater, as seen in Table 4.

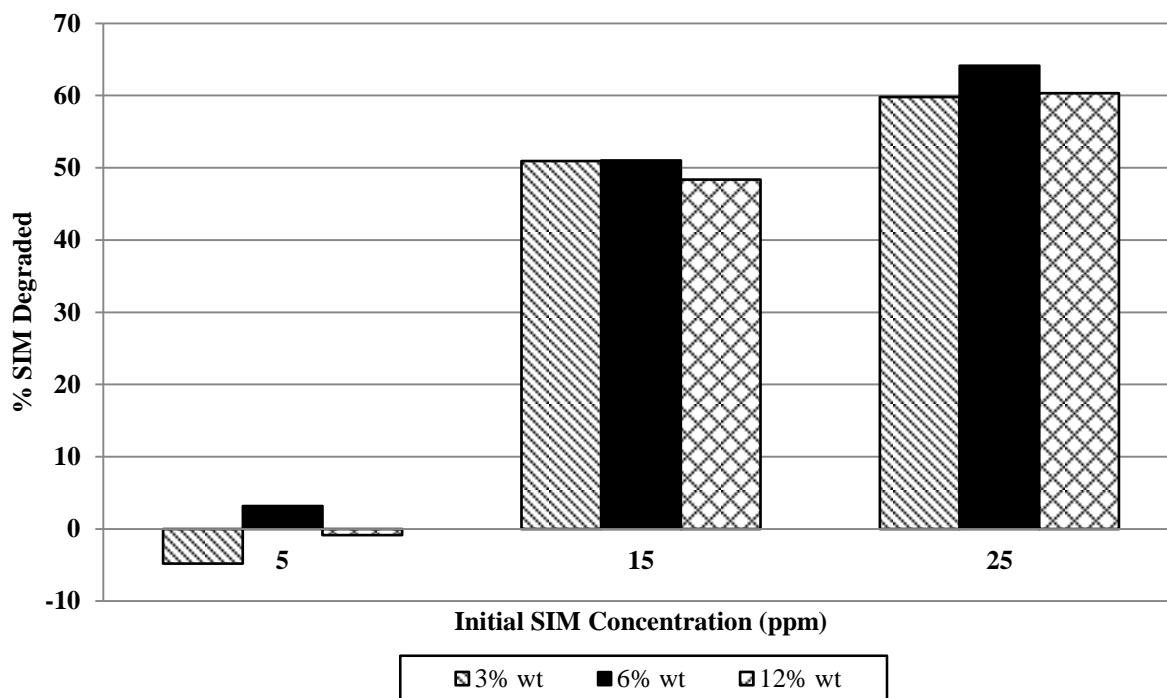

Figure 13: Percent simazine degradation at 5, 15, 25 ppm for ZnO/MoS₂ (3, 6, 12% wt)

Photocatalyst	Instantaneous Rate
ZnO/MoS ₂ 3%	1.71
ZnO/MoS ₂ 6%	0.811
ZnO/MoS ₂ 12%	1.28

Table 4: Instantaneous rates (10^{-3}) ($\text{mg}\cdot\text{L}^{-1}\cdot\text{s}^{-1}$) of degradation by Zn/MoS₂ (3, 6, 12%) at 20°C with an initial simazine concentration of 15 ppm

Band Gap Study

Photocatalyst	Band Gap (eV)
ZnO	3.37
ZnO/MoS ₂ 3%	3.17
ZnO/MoS ₂ 6%	3.22
ZnO/MoS ₂ 6% n/c	3.23
ZnO/MoS ₂ 12%	3.25

Table 5: Calculated band gap for ZnO/MoS₂ photocatalysts

Band gap values were calculated by the Kubelka-Munk fitting from % Reflectance data.

The Kubelka-Munk fitting method is based on the following equation:

$$F(R) = \frac{(1-R)^2}{2R}$$

where R is equal to the reflectance, $(1-R)^2$ is equal to the extinction coefficient, and $(2R)$ is equal to the scattering factor.⁴⁶ By plotting $F(R)$ as a function of energy (eV), the band gap can be extrapolated from the graph. When comparing the band gap for pure ZnO and the ZnO/MoS₂ heterostructures, there was a narrowing in valence and conductive band in all the ZnO/MoS₂ materials. By reducing the electrical potential of the material, the wavelength of radiation needed to initiate a photocatalytic process is closer to the visible light region. Wei *et al* reported similar band gap values when comparing the band gap of ZnO/MoS₂ quantum dots with that of pure ZnO.⁴¹

CHAPTER V

CONCLUSIONS

The photocatalytic activity of four ZnO/MoS₂ heterostructures was investigated. The photocatalysts varied in the percent by mass of MoS₂ present in the structure which ranged from 3 to 12%. X-ray diffraction and UV-Vis spectrophotometry were used to characterize the photocatalysts. The photocatalysts were tested on the ability to photo-catalytically degrade a triazine herbicide, simazine, under visible light. Reaction conditions such as the pH of simazine solution and the loading mass were investigated to determine the optimal conditions for efficient degradation.

The pH was varied from 2 to 8, and it was determined that pH 2 was the optimal pH for simazine degradation for all photocatalysts during a one-hour cycle. At pH 2, the amount of photocatalyst was varied from 10 to 80 mg. A loading mass of 20 mg was chosen for ZnO/MoS₂ (3, 6, 12%). With 20 mg of material 66.55%, 56.01%, and 57.43% of the simazine was degraded within one hour for 3, 6, and 12% wt respectively. The effects of altering the loading mass were more apparent with the 3% wt. A pH of 2 and loading mass of 20 mg was used for the kinetics and concentration variance studies.

With the reaction conditions optimized the rate of simazine degradation was investigated over a 2-hour period at three different temperatures (20,30, and 50°C). By graphically plotting the $\frac{1}{[SIM]}$ as a function of time it was evident that the degradation process proceeded through 2nd order kinetics. At 20°C the rates degradation was as follows, 3% wt ($6.93 \times 10^{-4} \text{ L} \cdot \text{mg}^{-1} \cdot \text{s}^{-1}$), 6%

wt ($4.56 \times 10^{-4} \text{ L} \cdot \text{mg}^{-1} \cdot \text{s}^{-1}$), 6 % wt noncommercial MoS_2 ($6.69 \times 10^{-4} \text{ L} \cdot \text{mg}^{-1} \cdot \text{s}^{-1}$), and 12% wt ($4.00 \times 10^{-4} \text{ L} \cdot \text{mg}^{-1} \cdot \text{s}^{-1}$). As the temperature increased from 20 to 50°C the rate of degradation increased. When the initial concentration of simazine was decreased from 25ppm to 15 ppm the percent of simazine degraded decreased from 59.78 to 50.947% for $\text{ZnO}/\text{MoS}_2_{3\%}$, from 64.13 to 51.04% for $\text{ZnO}/\text{MoS}_2_{6\%}$, and from 60.32 to 48.37% $\text{ZnO}/\text{MoS}_2_{12\%}$. When the concentration of simazine was 5 ppm the percent simazine degradation decreased to 0% for $\text{ZnO}/\text{MoS}_2_{3\%}$ and $\text{ZnO}/\text{MoS}_2_{12\%}$. $\text{ZnO}/\text{MoS}_2_{6\%}$ only 3% simazine degradation was observed.

In addition, the excess amounts of MoS_2 present in the heterostructure can hinder the photocatalytic efficiency of the material by interfering with light absorption by ZnO. For the heterostructures comprised of commercial MoS_2 the 3% wt performed better than the 6, and 12% wt. Although only one catalyst prepared with noncommercial MoS_2 was studied, the preliminary data suggests that by using noncommercial MoS_2 , which contains fewer layers, the degradation can be further enhanced.

UV-Vis spectrophotometric characterization of the photocatalysts yielded calculated band gap values less than that of pure ZnO, and greater than that of pure MoS_2 for all materials. This leads to the conclusion that by introducing MoS_2 to the structure of ZnO, the material can effectively function as a photocatalyst in the visible region.

X-ray diffraction characterization of the synthesized photocatalysts confirmed the presence of ZnO and MoS_2 in the heterostructure. The intensity of the diffraction peaks characteristic of ZnO remained the same for all materials. There was an increase in the intensity of the (002) diffraction peak for MoS_2 as the weighted percent of MoS_2 increased in the sample. When comparing the 6% heterostructures synthesized with and without commercial MoS_2 , it was found that the intensity of MoS_2 was significantly lesser in the sample with the noncommercial

MoS₂. The lower intensity in the 002 plane is possibly due to the decreased layers of MoS₂ in the noncommercial sample.

BIOGRAPHICAL SKETCH

Alexandria Castillo was born in 1996 in McAllen, Texas to Perfecto D. Castillo and Maria P. Castillo. She grew up in Alamo, Texas and attended PSJA Memorial Early College High School where she graduated in May of 2014. She attended South Texas College during high school and completed an Associate of Science in Biology in May of 2014. Alexandria attended the University of Texas at San Antonio from August 2014 to May 2017 and graduated Cum Laude with General Honors from the Honors College with a Bachelor of Science in Chemistry. In the Fall of 2017, she enrolled at the University of Texas Rio Grande Valley and began the working towards a Master of Science in Chemistry. At the University of Texas Rio Grande Valley Alexandria was employed as a Teaching Assistant, Research Assistant, and conducted research while completing the degree curriculum. Alexandria graduated with her Master of Science in Chemistry in December of 2019. Alexandria Castillo's permanent address is 701 Margret Street Alamo, Texas 78516. Her personal email address is alexandria.castillo01@gmail.com.
